Objective
- Educational awareness to symptomatic toxoplasmosis in military veterans with overseas field deployment.

Introduction
- Toxoplasmosis is caused by infection with the protozoan Toxoplasma gondii, an obligate intracellular parasite.
- T. gondii infects a large portion of the world's population, possibly 1/3, but uncommonly causes clinically significant disease.
- Immunologically impaired, fetuses, and newborns are most susceptible.
- Seroepidemiologic surveys in the United States report 11 percent of persons aged 6 to 49 are seropositive for T. gondii.
- There are four means of acquiring toxoplasmosis in humans:
  1. Ingestion of infectious oocysts from the environment
  2. Ingestion of tissue cysts in meat or contaminated fruits/vegetables
  3. Vertical transmission
  4. Transmission through an organ transplantation from an infected donor
- Primary infection in immunocompetent persons is usually asymptomatic; however, in some, infection can present as an acute systemic infection. The infection typically develops 5 to 23 days after exposure to the organism.
- Serologic testing is the usual form of diagnosis in these patients.
- Constitutional symptoms such as fever, chills, and sweats are common.
- The most common clinical manifestation of acute toxoplasmosis is bilateral, symmetrical, nontender cervical adenopathy.

Case Report
- A 37-year-old male presented with persistent swollen bilateral non-tender occipital lymph nodes of two months duration.
- He also endorsed an acute fluid filled blister on the penis, recurrent cold sores, and significant fatigue but denied any fevers, chills, night sweats, weight loss and recent travel.
- All immunizations are up-to-date and received through the army.
- One of his colleagues in the army reported to be currently seeking medical attention for a recent infection.
- Aspiration biopsy of the right occipital lymph node demonstrated granulomas and aggregates of histiocytes compatible with reactive hyperplasia. No evidence of malignancy found. Findings were suggestive of toxoplasmosis.
- Follow up T. gondii serological testing results were consistent with a recent infection.
- Toxoplasma gondii Ab IgM: 104 AU/ML (reference range 0.0-7.9)
- Toxoplasma gondii Ab IgG: >400 AU/ML (reference range 0.0-7.1)
- Patient was referred to Infectious Disease and supportive therapy was recommended.
- A three month follow-up showed improvement in symptoms.

Conclusion
- Acute infection is typically self-limited.
- Lymphadenopathy, with a solitary lymph node in the head and neck regions, being the most common presentation in immunocompetent patients.
- More severe manifestations include: pneumonitis, myocarditis, pericarditis, polymyositis, hepatitis, acute respiratory distress syndrome, encephalitis, or chorioretinitis.
- A 2-4 week pyrimethamine based antibiotic course is recommended for patients with acute systemic infections related to T. gondii.
- Whereas in patients with T. gondii related chorioretinitis, pyrimethamine with sulfadiazine and leucovorin is preferred.
- Adjuvant glucocorticoids should be included for patients with significant vitreous inflammation and retinal vasculitis. The former regimens are typically preferred to TMP-SMX, which can also be used.
- Education and appropriate protective measures for high-risk individuals, such as servicemen stationed overseas, may be beneficial.
- Preventive measures include: proper storage and adequate cooking of raw meats, using hot water and soap to clean cooking surfaces, avoiding unpasteurized non-bovine milk (e.g. goat’s milk), as well as wearing gloves and adequate handwashing when handling soil or areas where non-domesticated cat litter may be a contaminant.
- In conclusion, most cases of acute reactive toxoplasmosis are self-limited.
